ABSTRACT

An mobile device to monitor human activity using multiple sensors comprising a processing unit to provide a first estimation user activity data based on data from a first sensor, the first estimation having a first accuracy estimation, and to provide a second estimation of user activity data based on data from a second sensor, the second estimation having a second accuracy estimation, and the processor to calculate the user activity statistic based on the first estimation and the second estimation, wherein the calculated user activity statistic is a result of a weighted combination of the first estimation and the second estimation.

SENSOR FUSION FOR ACTIVITY IDENTIFICATION

This application is a continuation of U.S. patent application Ser. No. 14/061,701, filed on Oct. 23, 2013, now U.S. Pat. No. 8,784,309, issuing on Jul. 22, 2014, which is a continuation of U.S. patent application Ser. No. 13/476,962, filed on May 21, 2012, now U.S. Pat. No. 8,568,310, issued on Oct. 29, 2013, which is a divisional of U.S. patent application Ser. No. 12/202,206, filed on Aug. 29, 2008, now U.S. Pat. No. 8,187,182 issued on May 29, 2012.

FIELD OF THE INVENTION

This invention relates to using a plurality of sensors, and sensor fusion for more accurate calculation of user activity statistics.

BACKGROUND

The development of Micro-Electro-Mechanical Systems (MEMS) technology has enabled manufacturers to produce inertial sensors (e.g., accelerometers) that have a small size, cost, and power consumption. Global positioning system (GPS) sensors have also been developed that are of small size, cost and power consumption. Some manufacturers of unmanned aerial vehicles (UAVs) have begun using navigation systems that combine sensor readings of inertial sensors and sensor readings of GPS sensors via sensor fusion to improve navigation. UAVs always perform the same type of motions (flight in a forward direction). Therefore, the navigation systems are not required to identify different types of activities. Nor are the navigation systems capable of performing activity identification. Moreover, the navigation systems are also incapable of determining activity statistics associated with particular activities.

Recent advances have enabled inertial sensors and GPS sensors to be installed in a limited number of mobile commercial electronic devices such as cellular phones and portable computers. However, no such mobile devices are currently offered that perform sensor fusion to combine GPS sensor readings and inertial sensor readings.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention is illustrated by way of example, and not by way of limitation, and can be more fully understood with reference to the following detailed description when considered in connection with the following figures:

FIG. 1 is a block diagram illustrating an electronic device, in accordance with one embodiment of the present invention;

FIG. 2 illustrates a block diagram of an activity monitoring system, in accordance with one embodiment of the present invention;

FIG. 3 illustrates a flow diagram for a method of monitoring human activity using an inertial sensor and a location based sensor, in accordance with one embodiment of the present invention;

FIG. 4 illustrates a flow diagram for a method of monitoring human activity using an inertial sensor and a location based sensor, in accordance with another embodiment of the present invention;

FIG. 5A illustrates a flow diagram for a method of filtering user activities based on location information, in accordance with one embodiment of the present invention;

FIG. 5B illustrates a flow diagram for a method of filtering location information based on acceleration measurements, in accordance with one embodiment of the present invention;

FIG. 6 illustrates a flow diagram for a method of automatically initiating actions based on location measurements, in accordance with one embodiment of the present invention; and

FIG. 7 illustrates a flow diagram for a method of planning a route, in accordance with one embodiment of the present invention;

FIG. 8 illustrates a flow diagram for a method of tracking user progress along a defined path, in accordance with one embodiment of the present invention;

FIG. 9 illustrates a flow diagram for a method of calibrating a stride length correlation model, in accordance with one embodiment of the present invention; and

FIG. 10 illustrates a block diagram of a machine in the exemplary form of a computer system, in accordance with one embodiment of the present invention.

DETAILED DESCRIPTION

Embodiments of the present invention are designed to monitor human activity using multiple sensors. In one embodiment, a mobile device monitors accelerations using an inertial sensor. A user activity is identified based on the accelerations. Examples of user activities include walking, running, rollerblading, bicycling, etc. A first calculation is made of a user activity statistic associated with the user activity based on the accelerations. User activity statistics include periodic human motion counts, distance traveled, location, calories burned, etc. Location information is obtained by a location based sensor. A second calculation is made of the user activity statistic based on the location information. The final user activity statistic is calculated based on the first calculation and the second calculation.

FIG. 1 is a block diagram illustrating an electronic device **100**, in accordance with one embodiment of the present invention. Electronic device **100** may be a cellular phone, wrist watch, mp3 player, personal digital assistant (PDA), mobile game console, laptop computer, or any other device which can support at least two sensors and be carried by a user.

In one embodiment, the electronic device **100** is a portable electronic device that includes one or more inertial sensors **135** and one or more location based sensors **165**. The inertial sensor **135** may measure accelerations along a single axis or multiple axes, and may measure linear as well as rotational (angular) accelerations. In one embodiment, one or more inertial sensors together provide three dimensional acceleration measurement data.

The inertial sensor **135** may generate acceleration measurement data **175** continuously, or at a sampling rate that may be fixed or variable. In one embodiment, the inertial sensor **135** receives a timing signal from a timer (not shown) to take measurements at the sampling rate.

The location based sensor **165** can include a single location based sensor, or multiple location based sensors (e.g., multiple different types of location based sensors). In one embodiment, the location based sensor **165** includes a global positioning system (GPS) sensor, which may include a GPS antenna and a GPS receiver. The GPS sensor obtains location information from one or more GPS satellites.

In one embodiment, the location based sensor **165** includes a network localization sensor. A network localization sensor determines a position by receiving signals from multiple sources that have known locations, and calculating the posi-

tion based on the combined signals using trigonometric relations. Network localization sensors may determine location based on trilateration, multilateration and/or triangulation. The signals used to determine location may be radio frequency (RF) signals formatted according to the Bluetooth protocol, Zigbee protocol, wireless fidelity (WiFi) protocol, global system for mobile communications (GSM) protocol, 3G mobile communications protocol, etc. For example, a first network localization sensor may perform network triangulation using signals received from a mobile phone service provider's cell towers. In another example, a second network localization sensor may perform triangulation using wireless fidelity (WiFi) signals received from multiple nearby WiFi access points (e.g., hotspots).

In one embodiment, the location based sensor **165** includes a radio frequency identification (RFID) reader that reads transponders (e.g., passive integrated transponders (PITs)). Each transponder may report a specific location. When, for example, a transponder that reports location A is read, the location based sensor **165** knows to a high degree of certainty that the electronic device **100** is at location A. Alternatively, the location based sensor **165** may itself include a PIT that is read by an RFID reader at a known location. Upon the PIT being read by a particular RFID reader having a known location, the location based sensor **165** may learn its current location.

Multiple location based sensors **165** may be used separately or together. When used separately, each location based sensor **165** may independently determine a location of the electronic device **100**, and report the location to a location processor **170**. When used together, the capabilities of one location based sensor **165** can be used to augment the capabilities of another location based sensor **165**. Examples of such cooperative use of location based sensors **165** include assisted GPS and enhanced GPS, in which location data reported by a network localization sensor is used to augment a GPS sensor. A single location may then be reported to the location processor **170**.

The location based sensor **165** may generate location information continuously, or at a sampling rate that may be fixed or variable. In one embodiment, the location based sensor **165** receives a timing signal from a timer (not shown) to take measurements at the sampling rate. The location based sensor **165** may obtain location measurements at a sampling rate that is the same as or different from the sampling rate at which the inertial sensor **135** collects acceleration measurement data.

The location based sensor (or location based sensors) **165** can report a position of the electronic device **100** as a latitude and longitude, and may report a horizontal accuracy. In one embodiment, the horizontal accuracy of the location is reported as a confidence radius. For example, a location may be reported with a horizontal accuracy of 10 m, meaning that the reported location is accurate within a circle having a 10 m radius. Accuracy of the location may vary from about 10 m to about 300 m for location data obtained by a GPS sensor, depending on user location (e.g., in a city, under open sky, under a tree, in a building, etc.). The location information may further include an altitude, and may include a vertical accuracy. The location information may also include a time that the location was recorded.

In one embodiment, the inertial sensor **135** is coupled to a motion processor **120**. The motion processor **120** processes acceleration measurement data received from the inertial sensor **135** to identify user activities. Examples of user activities that can be identified include walking, running, rollerblading, bicycling, cross country skiing, and other repetitive motion-based activities. The motion processor **120** also estimates

user activity statistics based on the acceleration measurement data. User activity statistics may include multiple statistics associated with user activities (e.g., running and/or walking). Examples of user activity statistics include data about recent workouts, distance traveled per workout, distance traveled per day, average speed, highest speed, average incline of surface traveled, etc.

The motion processor **120** may identify a current user activity from a plurality of identifiable user activities. In one embodiment, the motion processor **120** identifies a user activity by monitoring for different events, each event indicative of a different type of activity. Events occur when certain motion criteria are satisfied (e.g., when a motion signature indicative of a step occurs within a certain period). In one embodiment, when enough events indicative of a particular user activity are detected, the motion processor **120** identifies the activity as being performed by the user. In one embodiment, events may include positive events (ones that must be met to classify a motion in a certain way) and negative events (ones that indicate that a motion cannot be classified certain way).

Once the motion processor **120** has identified a user activity, the motion processor **120** may apply a set of motion criteria specific to the identified activity to estimate one or more user activity statistics (e.g., to detect appropriate periodic human motions). Motion criteria may include acceleration thresholds (e.g., a step may be counted if the measured acceleration is below a first threshold and/or above a second threshold), acceleration comparison requirements (e.g., a step may be counted if a current measurement of acceleration is above or below one or more previous measurements of acceleration), cadence windows (e.g., a step may be counted if accelerations characteristic of a step occur within a certain timeframe as measured from a previous step), etc.

One type of user activity statistic that the motion processor **120** can determine is a number of steps (or other periodic human motions) taken. In one embodiment, a series of motion criteria are applied to the acceleration measurement data to detect steps or other periodic human motions. If each of the motion criteria are satisfied, a step may be identified, and counted. Alternatively, if a sufficient number of the motion criteria are satisfied, without a number of negative events, a step may be counted. In one embodiment, a different set of motion criteria may apply for running, for walking, and/or for other periodic human motions. For example, a first threshold and first cadence window may be used to determine if a step has occurred while a user is running, and a second threshold and second cadence window may be used to determine if a step has occurred while a user is walking.

Another type of user activity statistic that can be determined by the motion processor **120** is a distance traveled. A user's stride length can be determined for a step based on gait characteristics associated with the step. Examples of gait characteristics include step cadence, heel strike, and other gait characteristics that can be derived from acceleration measurements. For example, if a step cadence of 70 steps per minute and a specific heel strike are detected, a stride length of 2 ft. may be determined. Step detection and the calculated stride length of each step can then be used to calculate distance traveled.

In one embodiment, the stride length is determined by comparing gait characteristics to a stride length correlation model. The stride length correlation model correlates stride lengths to steps (or other periodic human motions) based on gait characteristics associated with the step (e.g., step cadence, heel strike, and other gait characteristics that can be derived from acceleration measurements). In one embodiment, the stride length correlation model includes a stride

5

length algorithm that identifies a specific stride length when one or more gait characteristics are used as input. The stride length algorithm may vary depending on user attributes (e.g., depending on user weight, height, athletic ability, etc.).

In one embodiment, the stride length correlation model includes a stride length data structure (e.g., a lookup table, tree, etc.) that has a collection of entries. Each entry may associate a specific set of gait characteristics with a specific stride length. For example, the data structure may include a first entry associating a cadence of 70 steps per minute with a stride length of 2.6 feet, a second entry associating a cadence of 100 steps per minute with a stride length of 3 feet, etc. Each entry in the data structure may be associated with a range of gait characteristics. Therefore, for example, the cadences of 5-10 steps per minute may all be associated with a stride length of 2 feet in an entry. The use of a data structure may require less computing power than the use of the algorithm. The greater the number of entries, the more accurate the data structure, but the more memory it may require.

Other user activity statistics that the motion processor **120** can estimate include calories burned, route traveled, average speed of travel, maximum speed of travel, workout intensity, vertical distance traveled, and so on. These user activity statistics may be determined based on knowledge of user attributes (e.g., user weight, height, age, athletic ability, etc.), current user activity, and acceleration measurement data.

In one embodiment, steps (or other periodic human motions) may be accurately counted, and speed and distance traveled may be accurately determined by the motion processor **120**, regardless of the placement and/or orientation of the electronic device **100** on a user. In a further embodiment, steps may be accurately counted, and speed and distance may be accurately determined, whether the electronic device **100** maintains a fixed orientation or changes orientation during use. In one embodiment, this can be achieved by monitoring the acceleration measurements to determine a dominant axis (axis that is most affected by gravity), and identifying a relationship between the axes of the inertial sensor and an orientation of the user based on the dominant axis.

In one embodiment, the motion processor **120** determines an accuracy of the calculated user activity statistics, as well as a confidence for the determined user activity. The accuracy can be determined based on the regularity (e.g., repeatability) of the user's motions, a number of positive events and negative events that are identified, motion criteria that are satisfied, etc. In one embodiment, the accuracy/confidence of the user activity and the user activity statistics are reported as a percentage of certainty. For example, the motion processor **120** may determine that there is a 94% likelihood that the user is walking at a cadence of 25 steps per minute. Alternatively, the confidence may be reported as a standard deviation, probability distribution, etc. In one embodiment, the motion processor **120** can report multiple user activities, and a likelihood that each is being performed. For example, the motion processor **120** may determine that there is a 35% likelihood that the user is running and a 65% likelihood that the user is speed walking.

In one embodiment, the map is used to plan a path between a starting location and an ending location. Path planning is described in greater detail below with reference to FIG. 7. In one embodiment, the map is used to direct a user through a path and/or to provide instructions to the user as the user traverses the path. Such an embodiment is described in greater detail below with reference to FIG. 8.

Referring to FIG. 1, in one embodiment, the location based sensor **165** is coupled to a location processor **170**. The location processor **170** processes location measurement data received from the location based sensor **165**. Based on the

6

location information, the location processor **170** estimates user activity statistics such as speed of travel, route traveled, etc.

In one embodiment, the location processor **165** receives location information from multiple location based sensors **165**. The location processor **170** may determine which of the location based sensor **165** is providing the most accurate location information, and use that location information to estimate user activity statistics. In one embodiment, the location processor **170** determines an accuracy of each of the user activity statistics that it estimates. The accuracy of the user activity statistics may be determined based on an accuracy of the location information reported by the location based sensor **165**.

In one embodiment, the location processor **170** includes a map (or has access to a map, such as from a web mapping service). The user location may be compared to the map to determine the type of terrain that the user is traveling on. For example, the location processor **170** may determine that the user is traveling on a paved sidewalk, on a dirt trail, on a track, in a building, etc.

In one embodiment, the location processor **170** automatically performs an action when a predetermined location is identified. The action may be initiating a run application, or another appropriate action. The predetermined locations may be configured by a user. Additionally, some predetermined locations may be set by default. For example, gym locations may be configured by default so that a sports training application is automatically launched if a user location matches a location of a gym. In one embodiment, locations of particular items of training equipment within a gym can also be set. These locations may be identified, for example, using an RFID reader. The electronic device **100** can then determine information about the training equipment on which a user is training to more accurately log a workout. Alternatively, the user may indicate such locations. Alternatively a map of the gym layout may be acquired, which specifies such locations.

In one embodiment, the location processor **170** can set the predetermined location and/or the action based on repeated user behavior. For example, if the user typically starts a run at a first location and stops the run at a second location, these locations may be automatically recorded into memory, and associated with a run application. Of course, as at a track, the first and the second location may be the same location. The run application may then automatically be started when the user is located at the first location, and may automatically be terminated when the user is located at the second location. Therefore, the user may perform a run, and have the run recorded, without having to manually launch a run application.

In one embodiment, the motion processor **120** is connected with the location processor **170**. The location processor **170** may send location information and/or estimated user activity statistics (including estimated accuracies) to the motion processor **120**. The motion processor **120** may compare the received data to the user activity and/or the user activity statistics estimated by the motion processor **120**. If the received data has a high accuracy and the user activity and/or estimated user activity statistic calculated by the motion processor **120** have a low accuracy, the motion processor **120** may determine a new user activity and/or estimate a new user activity statistic. For example, if the motion processor **120** had originally determined that the user activity is walking, and the location processor **170** reports with a high degree of accuracy that the user is traveling at a speed that exceeds a

user's maximum walking speed, the motion processor **120** may determine that the user is running, or that the user is riding in a car.

In one embodiment, if the location information (GPS-based, network triangulation, etc.) has a high accuracy, and the user activity and/or user activity statistics calculated by the motion processor have a low accuracy, the motion processor uses the location information to perform calibration. In one embodiment, the motion processor **120** calibrates a stride length correlation model using the location information.

In one embodiment, motion processor **120** calibrates a stride length correlation model based on received location information that identifies a distance traveled. Such received location information may be correlated to gait characteristics that were collected while the received distance was walked or run. This correlation may then be compared to the stride length correlation model. If the correlation based on the received location information does not match the stride length correlation model, then the stride length correlation model may be modified or replaced.

In one embodiment, calibrating the stride length correlation model includes generating a new data structure using a data structure generation algorithm. The data structure generation algorithm may use as inputs user attributes (e.g., height, weight, age, etc.) and/or a stride length vs. gait characteristic correlation determined based on received distance information. Therefore, a new data structure can be produced that is tailored to user attributes of a specific user and/or based on empirical data taken of the specific user. Each entry in the new data structure may be more accurate for the user than entries in an uncalibrated data structure.

In another embodiment, calibrating the stride length correlation model includes adjusting entries in an existing data structure. Such adjustments may include shifting entries (e.g., adjusting entry values up or down), compressing entries (e.g., causing entries to represent a smaller range of gait characteristics), stretching entries (e.g., causing entries to represent a greater range of gait characteristics), scaling entries (e.g., multiplying entries by a percentage or scaling factor), etc. Adjustments may be made based on one or more of user attributes and a stride length vs. gait characteristic correlation determined based on received distance information. For example, a global shift may be applied to entries if a user walked 1 mile, but a distance of 1.5 miles was measured. Such a global shift could include shifting down the entries to reflect that the actual stride length is shorter than represented by the data structure. Alternatively, if only a few entries in the data structure are off, then only those entries may be shifted.

In yet another embodiment, calibrating the stride length correlation model includes modifying a stride length algorithm. Constants and/or variables that apply to user attributes may be modified. Moreover, adjustments may be made to the algorithm based on a stride length vs. gait characteristic correlation determined based on received distance information.

Calibration logic **220** may further calibrate an incline adjustment factor (not shown). The incline adjustment factor may be applied to the stride length correlation data when an incline is detected. For example, when a user walks uphill, the user is likely to take smaller steps than when that user walks on level terrain. This difference in stride length may be accounted for using the incline adjustment factor. A value of the incline adjustment factor that is applied to the stride length correlation model may depend on a degree of incline and on user attributes. The incline adjustment factor may be calibrated in the manners discussed above with reference to the stride length correlation model.

The motion processor **120** may also send estimated user activity statistics to the location processor **170**. The location processor **170** may compare the received user activity statistics to user activity statistics estimated by the location processor **170** and/or to location information received from the location based sensor **165**. If the received user activity statistics have a high accuracy, the location processor **170** may use the received user activity statistics to determine that the location based sensor **165** has not locked in on a GPS signal yet, or to lower the accuracy rating of the location information from the location based sensor **165**.

In one embodiment, the motion processor **120** and location processor **170** are connected with a calculating logic **185**. The estimated user activity statistics determined by each of the location processor **170** and the motion processor **120** are reported to the calculating logic **185**, along with confidence interval of the estimations. The calculating logic **185** combines the two estimated user activity statistics to calculate more accurate final user activity statistics. The calculating logic **185** can use information from the motion processor **120** and the location processor **170** in conjunction to accurately count steps, determine speed of travel, determine distance traveled, etc.

In one embodiment, the calculating logic **185** applies a weight to each of the received user activity statistic estimations based on the reported accuracy of the estimations. The reported accuracy may range from around 1% accuracy to around 99% accuracy. In example, if the location processor **170** generated an estimation for a distance traveled that was 10 miles, with an 80% accuracy, and the motion processor **120** generated a distance traveled estimation of 11 miles with a 90% accuracy, these estimations may be combined as follows: $8/17(10)+9/17(11)=10.26$ miles. Alternatively, other algorithms may be used to combine the user activity statistics. For example, some user activity statistic estimations of the motion processor **120** may be weighted more heavily than those with an equivalent accuracy rating from the location processor **170**. In one embodiment, if an accuracy rating of a user activity statistic estimated by a processor falls below a threshold, the estimation associated with the accuracy rating is not used at all. In such an instance, the calculating logic **185** may completely rely upon the estimation of the other processor(s).

In one embodiment, the location based sensor **165**, inertial sensor **135** and calculating logic **185** are connected with a memory **110**. Memory **110** may include one or more of volatile memory (e.g., random access memory (RAM)), nonvolatile memory (e.g., read only memory (ROM), or flash memory), a hard disk drive, an optical drive, etc. Memory **110** may comprise multiple memories, i.e. a RAM memory used as a buffer, and a flash memory used to store other data. The location based sensor **165** and inertial sensor **135** store sensor data **175** (e.g., acceleration measurement data and location information) in memory **110**. In one embodiment, a buffer may collect acceleration measurement data and/or location information, and the buffered data may be used by motion processor **120** and/or location processor **170** for their calculations. In such an embodiment, motion processor **120** and/or location processor **170** may also be connected to memory **110**. In one embodiment, once the calculating logic **185** calculates user activity statistics **180**, it stores them in memory **110**.

In one embodiment, motion processor **120**, location processor **170** and calculating logic **185** are logics executed by a microcontroller **115**, field programmable gate array (FPGA), application specific integrated circuit (ASIC), or other dedicated processing unit. In another embodiment, one or more of

the motion processor **120**, location processor **170** or calculating logic **185** may be logics executed by a central processing unit. Alternatively, one or more of the motion processor **120**, location processor **170** or calculating logic **185** may include a state machine (e.g., an internal logic that knows how to perform a sequence of operations), a logic circuit (e.g., a logic that goes through a sequence of events in time, or a logic whose output changes immediately upon a changed input), or a combination of a state machine and a logic circuit.

FIG. 2 illustrates a block diagram of an activity monitoring system **200**, in accordance with one embodiment of the present invention. The activity monitoring system **200** may monitor the activity of one or more users connected thereto. Records of such user activity may be maintained by the activity monitoring system **200**. In one embodiment, the activity monitoring system **200** includes a mobile device **205** and a server **210**.

In one embodiment, the mobile device **205** operates in conjunction with the server **210** to determine step count, speed of travel, distance traveled, and/or other user activity statistics. In the illustrated embodiment, mobile device **205** and server **210** are connected via a network **210**, which may be a public network (e.g., internet) or private network (e.g., local area network (LAN), intranet, etc.). Alternatively, connections may be established directly between server **210** and mobile device **205**. Wireless connections may be established (directly between devices or via network **215**) using any wireless data transfer protocol, such as Bluetooth, radiofrequency (RF), wireless local area network (WLAN), infrared, cellular networks including global system for mobile communications (GSM), code division multiple access (CDMA), integrated digital enhanced network (iDEN), etc. Wired connections may be established using firewire, Ethernet, universal serial bus (USB), etc.

Mobile device **205** may be a mobile phone, PDA, pedometer, etc. In one embodiment, the mobile device **105** corresponds to electronic device **100** of FIG. 1. In a further embodiment, the mobile device **205** includes a motion processor **220** and a location processor **225**. The motion processor **220** and location processor **225** in one embodiment operate as described in FIG. 1 with reference to location processor **170** and motion processor **120**.

Motion processor **220** and location processor **225** are connected to a local calculating logic **230**. The local calculating logic **230** receives user activity statistic estimations from the motion processor **220** and location processor **225**, and calculates user activity statistics from the estimations on the fly (in real time). In the context of a sports application, this enables a user to be constantly apprised of his or her workout progress. However, in mobile devices **205** that have limited processing power, and/or that can dedicate only minimal processing power to the motion processor **220**, location processor **225** and local calculating logic **230**, the calculated user activity statistics may have reduced accuracy. To improve the accuracy of calculated user activity statistics, user activity statistics may be calculated by server **210** in one embodiment.

Server **210** may be a personal computer (desktop or laptop), network server, game kiosk, etc. Server **210** may receive user activity statistics, acceleration measurement data, user characteristics, etc. from the mobile device **205** directly or via the network **215**. In one embodiment, server **210** includes a remote calculating logic **235**. Remote calculating logic **235** uses the received user activity statistics, acceleration measurement data, user characteristics, etc. to recalculate the user activity statistics. The server **210** may have more processing power than mobile device **205**, and may calculate the user activity statistics to a higher level of accuracy. In one embodi-

ment, remote calculating logic **235** calculates user activity statistics, and transmits the calculated user activity statistics to the mobile device pseudo-real time. Such transmissions and calculations may be made pseudo-real time where a connection of sufficient bandwidth (a connection in which constant acceleration data, location data and user activity statistics can be transmitted with minimal lag) is established between the mobile device **205** and the server **210**. In another embodiment, the remote calculating logic **235** recalculates the user activity statistics after a user activity has ended (e.g., after the user has finished a run). The server **210** can reconstruct an entire user event/activity after the fact with increased accuracy.

FIG. 3 illustrates a flow diagram for a method **300** of monitoring human activity using an inertial sensor and a location based sensor, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **300** is performed by the electronic device **100** of FIG. 1.

Referring to FIG. 3, method **300** includes monitoring accelerations (block **305**). Monitoring accelerations may include obtaining acceleration measurement data from one or more inertial sensors and/or other acceleration monitoring devices. At block **310**, a motion processor processes the accelerations to identify a user activity. Examples of user activities that can be identified include walking, running, bicycling, rollerblading, etc. In one embodiment, the user activity is identified by monitoring for different events, each event indicative of a different type of activity. When enough events indicative of a particular user activity are detected, the user activity may be identified.

At block **315**, the motion processor makes a first estimation of a user activity. The user activity statistic may be estimated based on the acceleration measurement data. User activity statistics may include multiple statistics associated with user activities (e.g., running and/or walking). Examples of user activity statistics include data about recent workouts, distance traveled per workout, distance traveled per day, average speed, highest speed, average incline of surface traveled, etc. User activity statistics may be identified by applying a set of motion criteria specific to the identified activity. Motion criteria may include acceleration thresholds (e.g., a step may be counted if the measured acceleration is below a first threshold and/or above a second threshold), acceleration comparison requirements (e.g., a step may be counted if a current measurement of acceleration is above or below one or more previous measurements of acceleration), cadence windows (e.g., a step may be counted if accelerations characteristic of a step occur within a certain timeframe as measured from a previous step), etc.

At block **318**, a first accuracy of the first estimation is determined. The first accuracy may be in the form of a percentage of accuracy, a standard deviation, or other confidence rating.

At block **320**, a location processor obtains location information using a location based sensor. Examples of location based sensors include a GPS sensor, a network localization sensor, a transponder, etc. At block **325**, the location processor makes a second estimation of the user activity statistic based on the location information. At block **330**, the location processor determines accuracy for the second estimation.

At block **335**, a calculating logic weights the first estimation and the second estimation based on the first accuracy and the second accuracy. The calculating logic may be a local

11

calculating logic (e.g., that operates on a mobile device on which the location processor and motion processor operate) or a remote calculating logic (e.g., that is hosted by a server). At block **340**, the calculating logic calculates the user activity statistic based on the first estimation and the second estimation. The user activity statistic may be calculated on the fly, or after a user activity has ended. If this process was calculated at the end of the workout, the method then ends. If the process was calculated while the workout was still going on, the process returns to block **315** to continue monitoring.

FIG. **4** illustrates a flow diagram for a method **400** of monitoring human activity using an inertial sensor and a location based sensor, in accordance with another embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **400** is performed by the monitoring system **200** of FIG. **2**.

Referring to FIG. **4**, method **400** includes monitoring accelerations by a mobile device (block **405**). Monitoring accelerations may include obtaining acceleration measurement data from one or more inertial sensors and/or other acceleration monitoring devices. At block **410**, the mobile device obtains location information using a location based sensor. At block **415**, the accelerations and the location information are transmitted to an external computing device (e.g., a server). In one embodiment, the location information and accelerations are transmitted wirelessly (e.g., via WiFi, GSM, 3G, Bluetooth, etc.).

At block **420**, it is determined whether a user activity has ended. Such a determination may be made by the mobile device or by the external device. If the user activity has ended, the method proceeds to block **430**. If the user activity has not ended, the method proceeds to block **425**.

At block **425**, the mobile device receives a user activity statistic that has been calculated by the external computing device. In one embodiment, this user activity statistic may be displayed to the user. The method then returns to block **405** to continue monitoring for accelerations.

At block **430**, the mobile device receives a calculated final activity data, or reconstruction, of an event that includes multiple user activity statistics. The event may be a workout session (e.g., a run), and may include, for example, number of laps, distance traveled, route traveled, number of steps, average running speed, and so on. The final activity data may alter the activity data that was displayed to the user during the work-out. However, the final activity data will be more accurate, in one embodiment, since it will include data from multiple sensors.

FIG. **5A** illustrates a flow diagram for a method **500** of filtering user activities based on location information, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **500** is performed by the electronic device **100** of FIG. **1**.

Referring to FIG. **5A**, method **500** includes monitoring accelerations using an inertial sensor housed in a mobile device (block **505**). At block **510**, a motion processor processes the accelerations to identify a user activity. At block **515**, a location processor obtains location information using a location based sensor. In one embodiment, the location infor-

12

mation is a latitude and longitude. In one embodiment, a location processor utilizes map data to map the latitude and longitude to a map location.

At block **525**, the accuracy of the user activity is verified using the location information. The mobile device can determine, for example, whether a user location has changed too quickly for the identified user activity. For example, if the user is moving at a speed of around 50 mph, it can be determined that the user is not walking. For another example, if the user is jogging at a steady pace, but the location data indicates that the user is travelling through various buildings, there is a mismatch between the user activity and the map location information. If the location information excludes the identified user activity, the method proceeds to block **530**, and a new user activity is identified. In another embodiment, the accuracy rating of the user activity and/or location information is changed due to the mismatch.

If the location information does not exclude the calculated user activity, the method ends.

FIG. **5B** illustrates a flow diagram for a method **550** of filtering location information based on acceleration measurements, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **550** is performed by the electronic device **100** of FIG. **1**.

Referring to FIG. **5B**, method **550** includes monitoring accelerations using an inertial sensor housed in a mobile device (block **555**). At block **560**, a motion processor processes the accelerations to identify a user activity.

At block **565**, a location processor obtains location information using a location based sensor. At block **570**, the location processor obtains new location information using the location based sensor. At block **575**, the location processor compares the change in location to the user activity and/or the accelerations. If the user activity correlates to the change in location, the method ends. If the user activity does not correlate to the change in location, the method proceeds to block **585**, and the location information is disregarded. The method then ends.

FIG. **6** illustrates a flow diagram for a method **600** of automatically initiating actions based on location measurements, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **600** is performed by the electronic device **100** of FIG. **1**.

Referring to FIG. **6**, method **600** includes obtaining location information using a location based sensor (block **605**). At block **610**, a location processor determines whether a current location matches a location based trigger. The location based trigger may have been programmed by a user, or may have been automatically determined based on repeated user behavior. For example, if a user is detected to repeatedly begin a run at a particular location, a run application may be automatically initiated when the user is detected to be at the particular location. If the current location matches a location based trigger, the method proceeds to block **615**. Otherwise, the method ends.

At block **615**, a preconfigured action is automatically performed (e.g., starting a run application). The method then ends.

13

FIG. 7 illustrates a flow diagram for a method **700** of planning a route, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **700** is performed by the electronic device **100** of FIG. 1.

Referring to FIG. 7, at block **715**, an electronic device receives a starting point and an end point from a user. At block **720**, the electronic device receives a route length from the user. At block **722**, the method generates one or more possible paths between the starting point and the end point.

At block **725**, the method determines whether any constraints have been placed on paths between the starting point and the ending point. Examples of constraints include number of turns, amount of vertical distance traveled, preferred types of terrain to travel over, estimated time to completion, and so on. Constraints may also include specific waypoints. For example, a user may indicate that the path should pass through a first location and a second location. The user may further indicate that the path should pass through the first location before passing through the second location. If one or more constraints are placed on the path, the method proceeds to block **735**. If no constraints are placed on the path, the method proceeds to block **765**. In one embodiment, the possible paths are generated before a user has input constraints. Alternatively, the user may input constraints before the method generates possible paths.

At block **765**, possible paths are displayed to a user. The method then proceeds to block **748**.

At block **735**, the method determines whether there is at least one path that meets all constraints that have been specified by a user. If there is a path that meets all constraints, the method proceeds to block **745**. If no path meets all constraints, the method proceeds to block **740**.

At block **740**, user paths are displayed in an order of importance. Those paths that meet the most constraints are shown first (e.g., at the top of a list), while those paths that meet the fewest constraints are shown last, or not shown at all. In one embodiment, the constraints are each associated with an importance value. The importance value indicates how important it is to a user that a particular constraint be met. Those paths that meet constraints that have a high importance value appear are displayed before those that meet constraints that have a lower importance value. The importance value may be input by the user, or may be preconfigured.

At block **745**, paths that meet all constraints are displayed. In one embodiment, paths that do not meet all constraints are also displayed. Paths that do not meet constraints may be displayed as discussed with reference to block **740**. The method proceeds to block **748**.

At block **748**, a user selection of a path is received. At block **750**, the method determines whether the user selected a path that failed to meet all constraints. If the user did not choose a path that failed to meet all constraints (e.g., if there were no constraints, or if all constraints were met), the method ends. If the user chose a path that failed to meet all constraints, the method continues to block **755**, and the importance value of the constraints that were not met are lowered for future evaluations. The method then ends.

FIG. 8 illustrates a flow diagram for a method **800** of tracking user progress along a defined path, in accordance with one embodiment of the present invention. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on

14

a processing device), or a combination thereof. In one embodiment, method **800** is performed by the electronic device **100** of FIG. 1.

Referring to FIG. 8, at block **820**, the method tracks user location. User location may be tracked using one or more location based sensors.

At block **825**, the method determines whether the user is following a defined path. The defined path may be a track, trail, street, or other physically discernable path. The method may determine that the user is following such a defined path by comparing the user location to a map. The defined path may also be a predetermined path that has been selected by the user. For example, the user may input a destination, and a defined path may be determined that will lead the user from a current location or input starting location to the input destination. Such a predetermined path may not correspond to a physically discernible path such as a trail or street. If the user is following a defined path, the method proceeds to block **830**. Otherwise the method ends.

At block **830**, the method provides directions to the user. The directions may direct the user, for example, to change direction (e.g., turn right or left) at a specific location. The directions may be provided to the user to keep the user on the defined path. If the user veers from the defined path, the instructions may guide the user back to the defined path.

At block **835**, the method determines whether the user has arrived at an end of the defined path. If the user has arrived at the end of the defined path, the method ends. Otherwise, the method proceeds to block **840**.

At block **840**, the method determines whether the user has reached a waypoint. The waypoint may be a predetermined location that causes the method to perform an action. Examples of actions include providing waypoint data, performing calibration, playing music, etc. If the user has not reached a waypoint, the method returns to block **820**. If the user has reached a waypoint, the method proceeds to block **845**.

At block **845**, the method provides waypoint data. The waypoint data may include current location, user statistics associated with a current run (e.g., average speed, distance traveled, distance remaining in defined path, etc.), and so on. The method then returns to block **820**, and continues to track user location.

FIG. 9 illustrates a flow diagram for a method **900** of calibrating a stride length correlation model, in accordance with one embodiment of the present invention. In one embodiment, the method calibrates the stride length correlation model during a user activity. In another embodiment, the method calibrates the stride length correlation model after a user activity ends. The method may be performed by processing logic that may comprise hardware (e.g., circuitry, dedicated logic, programmable logic, microcode, etc.), software (such as instructions run on a processing device), or a combination thereof. In one embodiment, method **900** is performed by the electronic device **100** of FIG. 1.

Referring to FIG. 9, at block **925**, the method determines whether a user has completed a portion of a defined path. The defined path may have been generated as described with reference to FIG. 7. If the user has not completed a portion of the defined path, the method returns to block **925** and again determines whether the user has completed a portion of the defined path. If the user has completed a portion of the defined path, the method continues to block **930**.

At block **930**, the method determines whether the completed portion includes a segment that qualifies for calibration. In one embodiment, a segment of the path qualifies for calibration if the user's exact route through the segment of the

15

path can be determined to a high degree of accuracy. Such a determination may be made, for example, by laying GPS sensor data over a map, and determining that a user traveled over a physically discernible path such as a trail. In one embodiment, a segment of the path qualifies for calibration if a user traveled over the segment at a consistent pace (e.g., at a regular cadence). For example, if the user ran over the path at a relatively continuous pace of between 8 and 9 minutes per mile, then the segment may qualify for calibration. In one embodiment, a segment qualifies for calibration if the segment is at a consistent grade or slope (e.g., if the segment is flat). In one embodiment, a segment qualifies for calibration if it meets all of the above mentioned criteria, or alternatively if it meets some of the above mentioned criteria. Other criteria may also be used. If no segments of the completed portion qualify for calibration, the method returns to block 925. If a segment of the completed portion qualifies for calibration, the method proceeds to block 935.

At block 935, a first path length is determined for the qualifying segment based on accelerometer data. At block 940, a second path length is determined for the qualifying segment based on location measurement data (e.g., based on GPS sensor data).

At block 945, the method determines whether there is a difference between the first path length and the second path length. If there is no difference in the path lengths, the method ends. If there is a difference in the path lengths, the method proceeds to block 950.

At block 950, the method calibrates a stride length correlation model based on the location measurement data and the accelerometer data. The stride length correlation model may be calibrated as discussed above with reference to FIG. 1. The method then ends.

FIG. 10 illustrates a block diagram of a machine in the exemplary form of a computer system within which a set of instructions, for causing the machine to perform any one or more of the methodologies discussed herein, may be executed. FIG. 1 is one embodiment of a computer system that may be used with the present invention. It will be apparent to those of ordinary skill in the art, however that other alternative systems of various system architectures may also be used.

Returning to FIG. 10, a data processing system includes a bus or other internal communication means 1015 for communicating information, and a processor 1010 coupled to the bus 1015 for processing information. The system further comprises a random access memory (RAM) or other volatile storage device 1050 (referred to as memory), coupled to bus 1015 for storing information and instructions to be executed by processor 1010. Main memory 1050 also may be used for storing temporary variables or other intermediate information during execution of instructions by processor 1010. The system also comprises a read only memory (ROM) and/or static storage device 1020 coupled to bus 1015 for storing static information and instructions for processor 1010, and a data storage device 1025 such as a magnetic disk or optical disk and its corresponding disk drive. Data storage device 1025 is coupled to bus 1015 for storing information and instructions.

The system may further be coupled to a display device 1070, such as a cathode ray tube (CRT) or a liquid crystal display (LCD) coupled to bus 1015 through bus 1065 for displaying information to a computer user. An alphanumeric input device 1075, including alphanumeric and other keys, may also be coupled to bus 1015 through bus 1065 for communicating information and command selections to processor 1010. An additional user input device is cursor control device 1080, such as a mouse, a trackball, stylus, or cursor direction keys coupled to bus 1015 through bus 1065 for

16

communicating direction information and command selections to processor 1010, and for controlling cursor movement on display device 1070.

Another device, which may optionally be coupled to computer system 1000, is a communication device 1090 for accessing other nodes of a distributed system via a network. The communication device 1090 may include any of a number of commercially available networking peripheral devices such as those used for coupling to an Ethernet, token ring, Internet, or wide area network. The communication device 1090 may further be a null-modem connection, or any other mechanism that provides connectivity between the computer system 1000 and the outside world. Note that any or all of the components of this system illustrated in FIG. 10 and associated hardware may be used in various embodiments of the present invention.

It will be appreciated by those of ordinary skill in the art that any configuration of the system may be used for various purposes according to the particular implementation. The control logic or software implementing the present invention can be stored in main memory 1050, mass storage device 1025, or other storage medium locally or remotely accessible to processor 1010.

It will be apparent to those of ordinary skill in the art that the system, method, and process described herein can be implemented as software stored in main memory 1050 or read only memory 1020 and executed by processor 1010. This control logic or software may also be resident on an article of manufacture comprising a computer readable medium having computer readable program code embodied therein and being readable by the mass storage device 1025 and for causing the processor 1010 to operate in accordance with the methods and teachings herein.

The present invention may also be embodied in a handheld or portable device containing a subset of the computer hardware components described above. For example, the handheld device may be configured to contain only the bus 1015, the processor 1010, and memory 1050 and/or 1025. The handheld device may also be configured to include a set of buttons or input signaling components with which a user may select from a set of available options. The handheld device may also be configured to include an output apparatus such as a liquid crystal display (LCD) or display element matrix for displaying information to a user of the handheld device. Conventional methods may be used to implement such a handheld device. The implementation of the present invention for such a device would be apparent to one of ordinary skill in the art given the disclosure of the present invention as provided herein.

The present invention may also be embodied in a special purpose appliance including a subset of the computer hardware components described above. For example, the appliance may include a processor 1010, a data storage device 1025, a bus 1015, and memory 1050, and only rudimentary communications mechanisms, such as a small touch-screen that permits the user to communicate in a basic manner with the device. In general, the more special-purpose the device is, the fewer of the elements need be present for the device to function. In some devices, communications with the user may be through a touch-based screen, or similar mechanism.

It will be appreciated by those of ordinary skill in the art that any configuration of the system may be used for various purposes according to the particular implementation. The control logic or software implementing the present invention can be stored on any machine-readable medium locally or remotely accessible to processor 1010. A machine-readable medium includes any mechanism for storing or transmitting information in a form readable by a machine (e.g., a computer). For example, a machine readable medium includes read-only memory (ROM), random access memory (RAM),

17

magnetic disk storage media, optical storage media, flash memory devices, electrical, optical, acoustical or other forms of propagated signals (e.g. carrier waves, infrared signals, digital signals, etc.).

The following detailed description of embodiments of the invention makes reference to the accompanying drawings in which like references indicate similar elements, showing by way of illustration specific embodiments of practicing the invention. Description of these embodiments is in sufficient detail to enable those skilled in the art to practice the invention. One skilled in the art understands that other embodiments may be utilized and that logical, mechanical, electrical, functional and other changes may be made without departing from the scope of the present invention. The following detailed description is, therefore, not to be taken in a limiting sense, and the scope of the present invention is defined only by the appended claims.

In the foregoing specification, the invention has been described with reference to specific exemplary embodiments thereof. It will, however, be evident that various modifications and changes may be made thereto without departing from the broader spirit and scope of the invention as set forth in the appended claims. The specification and drawings are, accordingly, to be regarded in an illustrative rather than a restrictive sense.

What is claimed is:

1. An mobile device to monitor human activity using multiple sensors comprising:

a processing unit to provide a first estimation user activity data based on data from a first sensor, the first estimation having a first accuracy estimation, and to provide a second estimation of user activity data based on data from a second sensor, the second estimation having a second accuracy estimation;

the processor to calculate the user activity statistic based on the first estimation and the second estimation, wherein the calculated user activity statistic is a result of a weighted combination of the first estimation and the second estimation.

2. The mobile device of claim 1, comprising: the processing unit comprising a low power processor; and a central processor, the central processor to provide other functions.

3. The mobile device of claim 1, further comprising: the plurality of sensors including a location sensor and a motion sensor; and

the calculating logic to verify the calculated user activity based on location information.

4. The mobile device of claim 1, further comprising: a transmission system to transmit at least a subset of the data from the plurality of sensors to an external computing device, to generate the user activity statistic.

5. The mobile device of claim 2, wherein the externally calculated user activity statistic includes a reconstruction of an event that started when the user activity was initially detected and ended when the user activity ceased to be detected.

6. The mobile device of claim 1, wherein the user activity statistic is one of a distance traveled, a route traveled, a speed of travel, a current position or a periodic human motion count.

7. The mobile device of claim 1, wherein the first sensor and the second sensor are each one of: an inertial sensor and a location sensor.

8. The mobile device of claim 7, further comprising: the calculating logic to verify the calculated user activity based on location information from the location sensor.

18

9. The mobile device of claim 7, further comprising: the calculating logic to verify location information based on accelerations from the inertial sensor and past location information from the location sensor.

10. The mobile device of claim 1, further comprising: a central processing unit to receive location information from the location sensor, and when the location information indicates that a user is at a particular location, the central processing unit to automatically perform a pre-configured action.

11. The mobile device of claim 10, wherein the preconfigured action comprises one of: starting or ending a sports training application, starting or ending a run application, providing coaching, logging a workout, initiating another application, and altering an application setting.

12. The mobile device of claim 1, further comprising: a microcontroller to receive a starting and an ending point and generate a plurality of possible paths, and further to apply defined constraints on the path, and display the possible paths to the user for selection.

13. The mobile device of claim 12, wherein if the user selects a path that does not meet a defined constraint, the defined constrain is lowered in importance.

14. The mobile device of claim 1, further comprising: the processor to identify a path segment suitable for calibration of one of the sensors, and comparing path length for the path segment as measured by the first sensor and the second sensor, and configuring the sensor with a lower accuracy estimation.

15. An electronic device comprising:

a first sensor to receive a first set data;

a second sensor to receive a second set data;

a processor to calculate a first estimation of user activity data based on the first set of data, and a second estimation of the user activity data based on the second set of data;

the processor to calculate a user activity statistic based on the first estimation and the second estimation, wherein the calculated user activity statistic is a result of a weighted combination of the first estimation and the second estimation.

16. The electronic device of claim 15, wherein the electronic device is one of: a cellular phone, wrist watch, mp3 player, personal digital assistant (PDA), mobile game console, a tablet, and a laptop computer.

17. The electronic device of claim 15, further comprising: the first sensor and the second sensor selected from among: an inertial sensor and a location sensor; and the first estimation and the second estimation each having an accuracy estimation, wherein the weighted combination utilizes the accuracy estimations.

18. The electronic device of claim 15, further comprising: the processor to receive a starting and an ending point and generate a plurality of possible paths, and further to apply defined constraints on the path, and display the possible paths to the user for selection.

19. The electronic device of claim 18, wherein if the user selects a path that does not meet a defined constraint, the defined constrain is lowered in importance.

20. The electronic device of claim 15, further comprising: the processor to identify a path segment suitable for calibration of one of the sensors, and comparing path length for the path segment as measured by the first sensor and the second sensor, and configuring the sensor with a lower accuracy estimation.
